(Received 25 August 2015; published 9 December 2015)

We obtain the phase diagram of spin-imbalanced interacting Fermi gases from measurements of density profiles of 6Li atoms in a harmonic trap. These results agree with, and extend, previous experimental measurements. Measurements of the critical polarization at which the balanced superfluid core vanishes generally agree with previous experimental results and with quantum Monte Carlo (QMC) calculations in the Bardeen-Cooper-Schrieffer and unitary regimes. We disagree with the QMC results in the Bose-Einstein condensate regime, however, where the measured critical polarizations are greater than theoretically predicted. We also measure the equation of state in the crossover regime for a gas with equal numbers of the two fermion spin states.

DOI: 10.1103/PhysRevA.92.063616

Strongly interacting Fermi gases are found in a variety of settings, including superfluid 3He, quark matter, superconducting materials, and ultracold atomic gases [1–3]. The properties of such systems, including the nature of any superfluid or superconducting order, strongly depend on the interactions between particles. At sufficiently low temperatures the short-range interaction between opposite spin atomic fermions may be characterized by the parameter \(1/k_Fa\), where \(k_F\) is the Fermi momentum and \(a\) is the s-wave scattering length. For \(1/k_Fa > 1\), opposite spins may form tightly bound bosonic pairs which repel each other, thus creating a Bose-Einstein condensate (BEC) of molecules. For weaker attraction, where \(1/k_Fa < −1\), an ultracold atomic gas may form a conventional Bardeen-Cooper-Schrieffer (BCS) superfluid of loosely bound pairs. In between these extremes is the unitarity regime, \(-1 < 1/k_Fa < 1\), corresponding to resonant two-body interactions. This BEC-BCS crossover has been studied extensively over the past decade in the context of ultracold atomic Fermi gases [4–6].

When the two spin states have equal populations, the crossover between the BEC and BCS limits has no phase transitions as a function of \(1/k_Fa\). Additional phases can appear, however, when an effective magnetic field couples to the spin-\(\frac{1}{2}\) fermions, favoring an imbalance (or polarization) in the number of fermions in each spin state [7,8]. In thin-film electronic superconductors, such a coupling can come from a real in-plane magnetic field [9]. In the present setting of cold atomic gases, this imbalance is accomplished by creating unequal populations of the two hyperfine levels comprising the pseudo-spin-\(\frac{1}{2}\) system. In the BCS regime, a sufficiently large chemical potential difference, known as the Chandrasekhar-Clogston limit [10,11], will suppress pairing. A spin imbalance can be accommodated in the BEC regime, however, resulting in a Bose-Fermi mixture that remains a superfluid. The exotic Fulde-Ferrell–Larkin-Ovchinnikov (FFLO) state, featuring pairs with nonzero momentum, has been proposed as the ground state of a spin-imbalanced superconductor under certain conditions [12,13]. There have been no definitive observations of FFLO superconductivity, but an experiment on spin-imbalanced fermions confined to one dimension has produced a phase diagram with a large polarized region consistent with the FFLO state [14].

Neglecting any exotic superfluid phases (such as the FFLO state), the phase diagram of the three-dimensional (3D) spin-imbalanced Fermi gas as a function of interaction strength and polarization, exhibits four phases [15]: (i) fully polarized, noninteracting normal NFP, (ii) partially polarized normal NFP, (iii) partially polarized superfluid SFp, and (iv) un polarized superfluid SF0 [16]. Additionally, constraining the system to a fixed particle number leads to regions of phase-separated mixtures of these phases. The local polarization, defined as the effective magnetization divided by the density \(p = (n_↑ − n_↓)/(n_↑ + n_↓)\), vanishes in the SF0 phase, \(p = 1\) in the NFP phase, and \(0 < p < 1\) in the NFP and SFp phases. The majority and minority species are defined by \(n_↑ ≥ n_↓\).

Experimentally, atoms are generally trapped in potentials resulting in inhomogeneous density distributions. In the local-density approximation (LDA) the local state of the gas is determined by its local chemical potential, so the density profiles can reveal transitions between phases. Observations of phase separation in spin-imbalanced Fermi gases were obtained by direct in situ imaging of the density distributions [17–19] and by imaging the distributions in time of flight [20]. The distributions reported in Ref. [17] were out of equilibrium due to an evaporative depolarization mechanism at work in their highly elongated confining potential [21,22] and therefore could not be compared with distributions calculated assuming equilibrium. Density profiles obtained by Shin et al. at unitarity and on the BEC side of resonance [23] agree quantitatively with the theory of Bertain and Giorgini (BG) computed using the quantum Monte Carlo (QMC) method and the LDA [24]. In the unitary regime, these profiles contain a jump in the local polarization \(p\) that indicates a first-order phase transition between the superfluid and the normal phases [23,24]. Navon et al. measured thermodynamic properties of the imbalanced gas by extracting the equation of state from doubly integrated density profiles [25]. In this paper we report measurements of the density profiles of Fermi gases for \(-1 ≲ 1/k_Fa ≲ 2\) and use these measurements to better constrain the low-temperature phase diagram. These measurements largely confirm the results of previous investigations and extend the range of interactions studied.

Our method for producing an imbalanced degenerate gas in the lowest two hyperfine states of \(^6\)Li, \(F = 1/2, m_F = 1/2\)
shot-to-shot variation in indicated by the line’s thickness. We estimate a systematic uncertainty in the radii of 4 system. In (d) and (i), 0; and (e) and (j) 0.4. The uncertainty in 1/k_F a is as large as 0.07 based on a combination of a 10% systematic uncertainty and shot-to-shot variation in N_c, 3% uncertainty in the trap frequencies, and 2 G uncertainty in the bias magnetic field. Each plot is an average of 3–9 experimental realizations that have P within a range ∆P = 0.02 centered on the given value. Black, blue, and red curves correspond to the majority spin |↑⟩, minority spin |↓⟩, and their difference, respectively. In (a)–(e) the blue and black vertical lines indicate the mean of the minority and majority edges R_m and R_p, respectively, and the purple vertical lines indicate the radius of maximum column density difference R_c. In (f)–(j) the vertical green lines indicate the mean boundary of the SF0 core R_c. For each vertical line, the standard error of the mean is indicated by the line’s thickness. We estimate a systematic uncertainty in the radii of 4 µm, dominated by the resolution limit of our imaging system. In (d) and (i), P > P_c so that R_c = 0, and R_p is not meaningful.

(|↑⟩) and F = 1/2, m_F = −1/2, (|↓⟩), has been discussed previously in detail [14,17,19]. In brief, we sympathetically cool ⁶Li with ⁷Li in an Ioffe-Pritchard magnetic trap and then load the ⁶Li into a single-beam optical dipole trap formed by a focused infrared laser beam. We control the spin imbalance by varying the power of an adiabatic rf transfer from |↑⟩ to |↓⟩ at a field of 835 G. After the rf transfer, we evaporatively cool the cloud in the single-beam trap by reducing its depth. We evaporate at 835 G to study interactions on the BCS side of resonance we quickly ramp the field to 765 G before evaporation. After evaporation, atoms are loaded into the final trap formed by two focused infrared laser beams crossing at right angles while the single-beam trap is slowly (100 ms) ramped off. The crossed beams each have 1/e² radii of 55 µm × 235 µm, resulting in an ellipsoidal crossed-beam trap with a measured axial frequency of ω_z/2π = 78 Hz and measured radial frequencies of ω_x/2π = 248 Hz and ω_y/2π = 274 Hz, at a trap depth of 1.5 µK. The number of |↑⟩ atoms N ↑ is typically around 2 × 10⁵ and varies by about 10% shot to shot. The cloud polarization P = (N↑−N↓)/(N↑+N↓) varies from shot to shot by about 30% for a given rf power, so data must be postselected using the measured P. After loading into the crossed-beam trap, we ramp the magnetic field to its final value B at a rate from 0.4 to 2.0 G/ms; the final bias field has an uncertainty of 2 G.

We use in situ phase-contrast polarization imaging, described previously [14,28], to record the spatial distribution of the trapped atoms. The probe beam propagates perpendicular to the bias magnetic field, which is parallel to the axial trap direction. The column densities n_{c↑,↓}(x',z) of each spin state are extracted from two images taken within several microseconds of each other at different probe detunings. Here the imaging plane (x’,z) is rotated 30° from the (x,z) plane defined by the trap potential. To improve the signal-to-noise ratio, we fit n_c to find the cloud center (x’ = 0, z = 0) and then average the four quadrants to obtain the column density distributions of the majority n_{c↑}(x’,z) = [n_{c↑}(x’,z) + n_{c↑}(−x’,z) + n_{c↑}(x’,−z) + n_{c↑}(−x’,−z)]/4, minority n_{c↓}(x’,z), and their difference, which is related to the spin density. The top row of Fig. 1 shows the average of these column densities for several experimental realizations with fixed parameters, for several values of B and P. The majority and minority cloud radii R_p and R_m, respectively, are obtained from axial cuts of the column densities for each experimental run and then averaged over several runs. We also determine the radius R_c where the spin column density n_{c↑} − n_{c↓} is maximum (the cusp). Within the LDA, a cusp

![Figure 1](https://example.com/figure1.png)

**FIG. 1.** (Color online) (a)–(e) Axial cuts of the quadrant-averaged column density n_{c↑,↓}(z) and (f)–(j) their corresponding density profiles n_{c↑,↓}(x). Values of B and P are indicated for each column and the corresponding values of 1/k_F a are (a) and (f) 1.6; (b) and (g) 0.6; (c), (h), (d), and (i) 0; and (e) and (j) −0.4. The uncertainty in 1/k_F a is as large as 0.07 based on a combination of a 10% systematic uncertainty and shot-to-shot variation in N_c, 3% uncertainty in the trap frequencies, and 2 G uncertainty in the bias magnetic field. Each plot is an average of 3–9 experimental realizations that have P within a range ∆P = 0.02 centered on the given value. Black, blue, and red curves correspond to the majority spin |↑⟩, minority spin |↓⟩, and their difference, respectively. In (a)–(e) the blue and black vertical lines indicate the mean of the minority and majority edges R_m and R_p, respectively, and the purple vertical lines indicate the radius of maximum column density difference R_c. In (f)–(j) the vertical green lines indicate the mean boundary of the SF0 core R_c. For each vertical line, the standard error of the mean is indicated by the line’s thickness. We estimate a systematic uncertainty in the radii of 4 µm, dominated by the resolution limit of our imaging system. In (d) and (i), P > P_c so that R_c = 0, and R_p is not meaningful.
with a discontinuous derivative would indicate the location of a first-order phase transition for a uniform gas. These mean radii are indicated by the vertical lines in Fig. 1.

We reconstruct the density distributions $n_{\uparrow \downarrow}(r)$ using inverse Abel transforms of the averaged $n_{\uparrow \downarrow q}(r)$. The bottom row in Fig. 1 shows axial cuts of these density distributions. The SF$_0$ core radius $R_c$ is the radius at which the spin density first rises above zero. The mean radii for several experimental realizations are indicated by the vertical lines in the bottom row of Fig. 1. Experimentally, we determine $R_c$ by finding where the spin density first rises above the background spin density noise, which is the standard deviation of the spin density for $z > R_t$. To reduce bias toward obtaining smaller values of $R_c$ due to noise, we smooth the profiles with a 7-pixel-wide Hann window before computing $R_c$. We also confirm our determination of $R_c$ by fitting the spin density profiles near $R_c$ with a function that increases linearly from 0 for $z > R_c$; the fit results are consistent to within shot-to-shot variation.

Temperatures are measured by fitting the ferromagnetic wings of $n_{\uparrow \downarrow}$ for clouds with high $P$ to noninteracting Thomas-Fermi distributions. We find that for $B \geq 743$ G the fitted temperature $T \lesssim 0.08 T_F$, where $T_F \approx 1.5 \mu$K is the Fermi temperature of $N_i$ noninteracting atoms. For lower values of $B$, however, we measure higher temperatures, which are likely a result of heating from inelastic molecular decay collisions. At $B = 725$ G, for example, we find $T \approx 0.11 T_F$.

The boundary locations $R_t$, $R_s$, and $R_\sigma$ are plotted as functions of $P$ in Fig. 2 for several different interaction strengths $1/k_F a$ ranging from the BEC to the BCS regimes. These boundary radii are normalized by $R_t = (48N_i)^{1/6} \alpha_{t}(\omega_x \omega_y / \omega_z)^{1/6}$ the axial Thomas-Fermi radius for a noninteracting gas with $N_i$ atoms, where $\alpha_t = (\hbar / m \omega_z)^{1/2}$ is the axial harmonic-oscillator length. The interaction strength is determined from $k_F a = (48N_i)^{1/6} \alpha_{t} a_{t}^{-1}$, where $a_{t} = (\hbar^2 / m \omega_x \omega_y) \omega_z^{-1/6}$ is the mean harmonic-oscillator length and $B$ is the bias magnetic field. For a given $B$, the systematic variation in $N_i$ with $P$ produces up to a factor of 1.2 variation in $1/k_F a$. Due to this variation, experiments at a given field trace out the $P-1/k_F a$ phase diagram along nonvertical lines. To account for day-to-day variation in trap frequencies, we scale $R_c$ for all the data at a given $B$ so that $R_t / R_c$ goes to 1 as $P$ goes to 1; this variation is less than 5%.

FIG. 2. (Color online) (a)–(e) and (k)–(o) Radii extracted from density and column density profiles at several interaction strengths: the majority $R_t$ ( ), minority $R_s$ ( ), cusp $R_c$ ( ), and SF$_0$ core $R_\sigma$ ( ) radii as functions of $P$, scaled by the axial Thomas-Fermi radius $R_t$ of a noninteracting Fermi gas with $N_i$ particles. (f)–(j) and (p)–(t) Local polarization at the cloud center $p_0$ ( ) and at $R_c$, $p_\sigma$ ( ). Each data point is the average of several realizations of the experiment, binned with width $\Delta P = 0.02$. Some of the phase boundaries $R_t$, $R_s$, and $R_c$ could not be identified for small $P$ due to a poor signal-to-noise ratio and for high $P$ there is no identifiable $R_s$. In these instances, the data points are omitted. The values for $1/k_F a$ have uncertainty less than 0.07, resulting from 10% systematic uncertainty and shot-to-shot variation in $N_i$, 3% uncertainty in the trap frequencies, and a 2 G uncertainty in the bias magnetic field. However, due to systematic variation of $N_i$ with $P$, $1/k_F a$ varies with $P$ for a given $B$, particularly in the deep BCS and BEC regimes. In these cases, we list a range of values from $1/k_F a$ at $P = 0$ to the value at $P = 1$; otherwise, we list the mean value. For each interaction strength, $R_c$ decreases as $P$ increases, until vanishing at $P_c$ (green arrows), which we determined with a fit (see the text). We also fit $p_\sigma$ to determine $P_c$ (orange arrows), as described in the text.
The radii plotted in Fig. 2 provide detailed information about the phases of trapped imbalanced Fermi gases as a function of the imposed population imbalance. One common feature is the existence of a balanced SF0 core with radius \( R_c \), that decreases with increasing \( P \) until it vanishes at a critical cloud polarization \( P_c \). To extract \( P_c \), we fit \( R_c(P) \) for each field, shown by the green data points in Fig. 2, to an empirical function which vanishes as \((P - P_c)^{1/2}\) for \( P < P_c \). The results are indicated by vertical green arrows in Fig. 2. At unitarity, we measure \( P_c = 0.79(4) \), where the error bar accounts for the uncertainty in measuring \( P \) for a single cloud as well as systematic uncertainty in the best-fit parameters.

This result is in good agreement with previous measurements giving \( P_c = 0.77 \) [18], 0.76(3) [29], and 0.75 [25] and with theoretical predictions of \( P_c = 0.77 [24, 30] \), all slightly higher than an initial measurement of \( P_c = 0.70(3) [20] \).

The work of BG, following earlier calculations of Pilati and Giorgini [16], involved calculating the phase diagram of trapped Fermi gases by combining the LDA with fits to QMC calculations to characterize the ground-state energies of the strongly interacting balanced SF0 phase and the partially polarized normal phase \( N_{sp} \). The ground-state energy of the SF0 was taken to consist of contributions from a balanced superfluid of pairs (given by the SF0 equation of state), a non-interacting Fermi gas of the excess \( |\uparrow\rangle \) spins, and a leading-order interaction between \( |\uparrow\rangle \) spins and pairs characterized by the atom-pair scattering length \( p_{a} \). Work by Alzetto and Leyronas found a higher-order correction with strength proportional to \( n_{\uparrow} (n_{\downarrow} - n_{\uparrow})^{2/3} [31] \). However, we find that including this correction [contained in Eq. (53) of Ref. [31]] within the BG formalism does not appreciably alter the value of \( P_c \) for any interaction strength. Thus, we expect the BG result for \( P_c \) as a function of interaction strength to be a robust theoretical prediction that we can test with our measurements.

We also determine \( P_c \) by finding the value of \( P \) where the local polarization at the center of the cloud \( p_{0} = p(z = 0) \) first rises above zero by fitting \( p_{0}(P) \) to a function that increases with \( P \) for \( P > P_c \). For \( 1/k_F a > 0.5 \), where we find a continuous SF0-SFp phase boundary, we assume that \( p_{0}(P) \) increases with a sum of terms going like \((P - P_c)^{3/2}\) and \((P - P_c)^{5/2}\). This form is motivated by the mean-field result for the magnetization \( M \) vs chemical potential difference in the SF0 state of a 3D Fermi gas [8]

\[
M = \frac{2}{3} \frac{m^{3/2}}{\sqrt{2\pi}^2 h^3} (\sqrt{\hbar^2 - |\Delta|^2} - |\mu|)^{3/2} \Theta(h - h_c), \tag{1}
\]

with \( m \) the atom mass, \( h \) the chemical potential difference, \( \mu \) the chemical potential, and \( \Delta \) the local pairing amplitude. As can be seen by the presence of the Heaviside step function \( \Theta(h - h_c) \), the magnetization is nonzero only for \( h > h_c = \sqrt{|\mu|^2 + \Delta^2} \) and close to \( h_c \) the onset of \( M \) is a sum of terms going as \((h - h_c)^{3/2}\) and \((h - h_c)^{5/2}\). If we furthermore assume that, at low \( P \), the cloud polarization scales linearly with \( h \), then we have justified our assumed form for the behavior of \( p_{0}(P) \), allowing us to extract \( P_c \).

Away from the deep BEC regime, for \( 1/k_F a < 0.5 \), where we find a first-order phase transition SF0 → \( N_{sp} \) [24], we fit \( p_{0}(P) \) with a function that is linear in \( P - P_c \), the expected magnetization for a Pauli paramagnetic phase. The values of \( P_c \) obtained from these fits are indicated by vertical orange arrows in Fig. 2. While our two methods should ideally produce the same \( P_c \), they differ slightly because we only consider non-negative radii, which leads to slight overestimates of \( R_c \) near \( P_c \) when averaging several profiles. The magnitude of this effect is smaller than the uncertainty in determining \( P_c \).

Furthermore, due to noise in the density profiles, we cannot distinguish an SF0 core from an SFp phase with \( P < 0.03 \).

The dependence of the critical polarization \( P_c \) on \( 1/k_F a \) determined by both methods is shown in Fig. 3. Here \( P_c \) reaches a maximum near \( 1/k_F a \sim 0.7 \) and decreases as the interactions are tuned in either direction. Our measured values of \( P_c \) agree with the values from Zwierlein and co-workers [18, 20] and Navon and co-workers [25, 29] for \( 1/k_F a \leq 0.75 \), where our measurement ranges overlap. Our measurements also agree with the zero-temperature theory of BG [24] in this regime.

According to theory, \( P_c \) begins to drop for \( 1/k_F a > 0.7 \), as the BCS pairs transition to more tightly bound bosonic molecules [16]. As \( 1/k_F a \) increases, the superfluid becomes more bosonic in character than fermionic, and since the bosonic superfluid can accommodate free fermions, the SF0...
core begins to vanish. For \(1/k_F a < 0.7\), the transition from SF\(_0\) to N\(_{FP}\) is predicted to be first order, while for \(1/k_F a > 0.7\) the transition from SF\(_0\) to SF\(_T\) is continuous [16]. In this Bose-Fermi regime, we observe critical polarizations for loss of the unpolarized core to be somewhat higher than predicted by BG [24]. It is unlikely that this discrepancy is due to the elevated temperatures we obtain in the BEC regime, since \(P_c\) is expected to decrease with increasing \(T\) [32]. Thus, the effect of finite \(T\) is to diminish the SF\(_0\) phase in favor of the SF\(_T\) phase, while we actually observe a more robust SF\(_0\) phase. Another possible explanation is that the discrepancy arises from the experimental challenge of observing a small central polarization that increases from zero continuously with increasing \(P\), rather than as a first-order jump, as in the BCS regime.

As we have discussed, the critical polarization \(P_c\) indicates where the balanced superfluid core of a trapped gas disappears. The data also reveal information about the uniform density phase diagram, assuming the LDA holds. To study these phase boundaries, we measure the local polarization \(p_s\) at the radius of maximum column density difference \(p_s = \rho(R)\) for each cloud. According to the LDA, jumps in the atom density as a function of chemical potential in a uniform imbalanced gas lead to jumps in the density profile in the trapped gas. These jumps occur at radii of maximum column density difference, implying that \(p_s\) can indicate the critical polarization for a first-order phase transition in the uniform system [24].

In Fig. 2 the second and fourth rows show the dependence of \(p_s\) on the cloud polarization \(P\). We can identify three distinct regimes showing qualitatively different behavior. First, in the deep BEC regime, for \(1/k_F a > 0.7\), we observe that \(p_s\) increases to 1 as \(P\) goes to 1. This behavior indicates that, in this regime, \(p_s\) does not measure the position of a uniform system phase boundary within the LDA, but is instead simply a local maximum of \(\rho\) within an SF\(_T\) phase. In this coupling range, therefore, the critical polarization for the superfluid transition of a uniform gas is \(p_s = 1\) [32].

Near the unitary region, for \(1/k_F a < 0.3\), we see that \(p_s\) is approximately independent of \(P\) for a wide range of \(P\) [see, e.g., Fig. 2(p)]. The presence of the plateau indicates that the LDA holds and that the point of maximum column density difference indeed represents a jump in \(\rho\) and a corresponding phase transition in the uniform system at \(p_s\) between SF\(_0\) and N\(_{FP}\) phases. We take \(p_s\) to be the mean value of the plateau for \(P < P_c\).

Finally, in between these two regimes, for \(0.3 < 1/k_F a < 0.7\), we find that \(p_s\) increases monotonically with \(P\), but that \(p_s = 1\) is never reached. This is the regime, predicted by BG, in which there is an SF\(_T\) phase, but only for sufficiently small \(P\). Here we take \(p_s\) to be the asymptotic value of \(p_s\) evaluated at \(p_s\). The values of \(p_s\) extracted in these regimes are plotted in the phase diagram (Fig. 4) and show excellent agreement with QMC calculations [16].

Possible evidence for finite temperature, and perhaps finite imaging resolution, is the absence of clear jumps in the minority density profiles shown in Fig. 1 for the unitarity and BCS regimes where a first-order transition between SF\(_0\) and N\(_{FP}\) phases is expected. Systematic effects are also evident in the phase diagrams of Fig. 2. In the unitarity and BCS regimes, \(R_s\) should correspond to \(R_c\), whereas in the BEC regime for
EOS can be expressed as $\xi(0) = (R_p/R_z)^4$, where $R_p$ is the radius of the superfluid core and $R_z$ is the Thomas-Fermi radius of a noninteracting gas with $N_z$ particles [33,34]. Although $(R_p/R_z)^4$ only approximates the EOS away from unitarity, we nonetheless present our measurements of this quantity in Fig. 5 and compare them with previous measurements and theoretical calculations of the EOS. In the BEC regime, we fit the column density profiles to a sum of Thomas-Fermi and the theoretical calculations of the EOS. In the BEC regime, we nonetheless present our measurements of this quantity in the BEC regime than predicted by theory. Although this discrepancy may be explained by very small polarizations that are difficult to detect, the data show that we are able to resolve $p_0$ as small as 0.03. It may also be possible that small adjustments to the theory could result in relatively large changes to $p_0$. Finally, we have measured the equation of state in the crossover regime, which is consistent with theory from the BCS to the BEC regimes.

In conclusion, we have measured density profiles of spin-imbalanced Fermi gases across the BEC-BCS crossover. From these profiles, we determined the critical polarization for both harmonically trapped and uniform gases above which the balanced superfluid phase SF$_0$ is suppressed. The agreement with previous measurements and QMC theory is generally good, although we find a more robust SF$_0$ core in the BEC regime than predicted by theory. Although this discrepancy may be explained by very small polarizations that are difficult to detect, the data show that we are able to resolve $p_0$ as small as 0.03. It may also be possible that small adjustments to the theory could result in relatively large changes to $p_0$. Finally, we have measured the equation of state in the crossover regime, which is consistent with theory from the BCS to the BEC regimes.
